AB - An **architecture** and memory mapping technique for an **extended** multiprocessor (XMP) computer system are provided to overcome physical/electrical limitations of single bus **architecture** while maximizing bus bandwidth utilization. The XMP computer system includes **multiple** SMP **nodes** each including an XMP interface and a **repeater structure**. The SMP **nodes** are connected to each other by unidirectional point-to-point links. The **repeater structure** in each SMP **node** includes an upper level bus coupled to one or more transaction repeaters. Each transaction repeater broadcasts transactions to bus devices attached to separate lower level buses. Transactions originating in a particular SMP **node** are stored in a queue, whereas transactions originating in other SMP **nodes** bypass the incoming queue to the bus device. **Multiple** transactions may be simultaneously broadcast across the point-to-point link connections between the SMP **nodes** in a defined, uniform order. Each of the n SMP **nodes** is assigned 1/n of the total address space. Cache coherency information is stored for the memory in each SMP **node**.

Memory regions may be assigned to operate in one of three modes: normal, migratory, or replicate. When operating in normal mode, transaction to an address space assigned to a particular **node** are tried only locally in that **node** first. In migratory mode transactions are always sent globally. And in replicate mode duplicate copies of the replicate memory region are assigned to each SMP **node** so that transactions are always tried locally first, and only sent globally if an improper cache coherency state is returned.
